Electron microscopy in situ hybridization (EM-ISH) represents a powerful method that enables the localization of specific sequences of nucleic acids at high resolution. We provide here an overview of three different nonisotopic EM-ISH approaches that allow the visualization of nucleic acid sequences in cells.

In situ hybridization at the electron microscope level: hybrid detection byautoradiography and colloidal gold. Hutchison NJ, Langer-Safer PR, Ward DC, Hamkalo BA. In situ hybridization has become a standard method for localizing DNA or RNAsquences in cytological preparations. We developed two methods to extend thistechnique to the transmission electron microscope level using mouse satellite DNAAybridization to whole mount metaphase chromosomes as the test system.

In situ hybridization of wild type Drosophila embryos at different developmental stages for the RNA from a gene called hunchback. In situ hybridization (ISH) is a type of hybridization that uses a labeled complementary DNA, RNA or modified nucleic acids strand (i.e., probe) to localize a specific DNA or RNA sequence in a portion or section of tissue (in situ) or if the tissue is small enough (e.g., plant seeds, Drosophila embryos), in the entire tissue (whole mount ISH), in cells, and in ...

In-situ hybridization—Wikipedia

In situ hybridization enables the detection and precise localization of a specific nucleic acid sequence within an individual cell. The nucleic acid sequence is bound specifically in a tissue section by complementary base pairing, that is, hybridization, with a detectable nucleic acid segment called a probe. In situ hybridization (ISH) combines three main advantages: great sensitivity, precise anatomical localization, and the possibility of quantification.

Fluorescence in situ hybridization is a molecular cytogenetic technique that uses fluorescent probes that bind to only those parts of a nucleic acid sequence with a high degree of sequence complementarity. It was developed by biomedical researchers in the early 1980s to detect and localize the presence or absence of specific DNA sequences on chromosomes. Fluorescence microscopy can be used to find out where the fluorescent probe is bound to the chromosomes. FISH is often used for finding specifi

Although SARS-CoV-2 is visualized on electron microscopy, there is an increasing demand for widely applicable techniques to visualize viral components within tissue specimens. Viral protein and RNA can be detected on formalin-fixed paraffin-embedded (FFPE) tissue using immunohistochemistry (IHC) and in situ hybridization (ISH), respectively.

Abstract. In the great majority of cases in situ hybridization is used to localize mRNA species at the tissue level, or DNA at the chromosome level. These approaches are generally best done by light microscopy. There are instances, however, when it becomes important to localize nucleic acids at the subcellular level—this brings us into the domain of the electron microscope.

The introduction in the late 1960s of in situ hybridization (ISH) techniques (Buongiorno-Nardelli and Amaldi 1970; Gall and Pardue 1969; John et al. 1969) opened a new era in histology and cell biology. Whereas immunocytochemical methods can demonstrate only the presence of synthesized protein molecules, irrespective of any routing in the tissue, the recognition in a tissue and in a cell of specific DNA or RNA sequences defines the precise location of a potential or an effective synthesis ...

In situ hybridization is used to reveal the location of specific nucleic acids sequences on chromosomes or in tissues. Visualization of the location of genes on chromosomes or of specific mRNAs or viruses in tissues is crucial for understanding the organization.
